Edited by Michael L. Klein, Temple University, Philadelphia, PA, and approved September 26, 2018 (received for review July 27, 2018)

Bioimaging plays an important role in cancer diagnosis and treatment. However, imaging sensitivity and specificity still constitute key challenges. Nanotechnology-based imaging is particularly promising for overcoming these limitations because nanosized imaging agents can specifically home in on tumors via the “enhanced permeation and retention” (EPR) effect, thus resulting in enhanced imaging sensitivity and specificity. Here, we report an original nanosystem for positron emission tomography (PET) imaging based on an amphiphilic dendrimer, which bears multiple PET reporting units at the terminals. This dendrimer is able to self-assemble into small and uniform nanomicelles, which accumulate in tumors for effective PET imaging. Benefiting from the combined dendrimeric multivalence and EPR-mediated passive tumor targeting, this nanosystem demonstrates superior imaging sensitivity and specificity, with up to 14-fold increased PET signal ratios compared with the clinical gold reference 2-fluorodeoxyglucose ([\textsuperscript{18}F]FDG). In addition, it is endowed with an excellent safety profile and favorable pharmacokinetics for PET imaging. Consequently, this dendrimer nanosystem constitutes an effective and promising approach for cancer imaging. Our study also demonstrates that nanotechnology based on self-assembling dendrimers provides a fresh perspective for biomedical imaging and tumor diagnosis.

dendrimer | supramolecular nanomicelle | bioimaging | EPR effect | tumor diagnosis

---

Early and precise diagnosis constitutes an essential step for successful management of many diseases, and cancer in particular. Although the advancement of molecular imaging has greatly improved cancer detection and diagnosis, tumor imaging using noninvasive techniques still faces problems relating to detection sensitivity, spatial resolution, and depth penetration, which affect the imaging quality and accuracy. Application of nanotechnology to the specific delivery of imaging agents to tumor lesions is widely expected to overcome these limitations and bring breakthroughs in cancer imaging and diagnosis (1, 2). This is because nanosized agents can specifically enter into and accumulate within tumor lesions via the “enhanced permeation and retention” (EPR) effect thanks to the leaky vasculature and dysfunctional lymphatic drainage in the tumor microenvironment (3–5). The EPR effect—also referred to as passive tumor targeting—can potentially boost the local concentration of the imaging agent in tumors, thereby improving imaging sensitivity and resolution (1, 2).

Self-assembly is a very powerful approach to create nanosystems in a modular and specific way, yet with relatively little synthetic effort (6). Recently, self-assembled supramolecular nanostructures formed from amphiphilic dendrimers (7–9) have emerged as innovative and effective drug delivery systems. These amphiphilic dendrimers couple the self-assembling feature of lipids with the well-defined dendritic structure and stability of dendrimers to generate nanocarriers with appropriate sizes, tailored properties, and high drug loading (8, 10, 11). For imaging, we reasoned that the dendritic multivalency of these specific amphiphiles could offer, upon conjugation, the unique capacity of carrying abundant copies of the contrast or imaging agents, ultimately resulting in better and more precise imaging. Accordingly, in this proof-of-concept study, we report a self-assembling amphiphilic dendrimer nanosystem that combines EPR-mediated tumor accumulation with the multivalent feature of dendrimer for effective tumor imaging using positron emission tomography (PET) (Fig. 1).

PET imaging is, among various noninvasive functional imaging modalities, commonly used in nuclear medicine to assess pathological functions. It has gained wide acceptance in cancer diagnoses and treatments. However, imaging sensitivity and specificity still constitute key challenges. Nanotechnology-based imaging is particularly promising for overcoming these limitations because nanosized imaging agents can specifically home in on tumors via the “enhanced permeation and retention” (EPR) effect, thus resulting in enhanced imaging sensitivity and specificity. Here, we report an original nanosystem for positron emission tomography (PET) imaging based on an amphiphilic dendrimer, which bears multiple PET reporting units at the terminals. This dendrimer is able to self-assemble into small and uniform nanomicelles, which accumulate in tumors for effective PET imaging. Benefiting from the combined dendrimeric multivalence and EPR-mediated passive tumor targeting, this nanosystem demonstrates superior imaging sensitivity and specificity, with up to 14-fold increased PET signal ratios compared with the clinical gold reference 2-fluorodeoxyglucose ([\textsuperscript{18}F]FDG). In addition, it is endowed with an excellent safety profile and favorable pharmacokinetics for PET imaging. Consequently, this dendrimer nanosystem constitutes an effective and promising approach for cancer imaging. Our study also demonstrates that nanotechnology based on self-assembling dendrimers provides a fresh perspective for biomedical imaging and tumor diagnosis.

Significance

Nanotechnology-based imaging is expected to bring breakthroughs in cancer diagnosis by improving imaging sensitivity and specificity while reducing toxicity. Here, we developed an innovative nanosystem for positron emission tomography (PET) imaging based on a self-assembling amphiphilic dendrimer. This dendrimer assembled spontaneously into uniform supramolecular nanomicelles with abundant PET reporting units on the surface. By harnessing both dendrimeric multivalence and the “enhanced permeation and retention” (EPR) effect, this dendrimer nanosystem effectively accumulated in tumors, leading to exceedingly sensitive and specific imaging of various tumors, especially those that are otherwise undetectable using the clinical gold reference 2-fluorodeoxyglucose ([\textsuperscript{18}F]FDG). This study illustrates the power of nanotechnology based on self-assembling dendrimers to provide an effective platform for bioimaging and related biomedical applications.
oncologic imaging mainly because of its excellent sensitivity up to the femtomolar range, with quantitative imaging capabilities and limitless depth of penetration (12, 13). Moreover, hybrid cameras enable precise anatomic localization of PET functional imaging via coregistration with X-ray computed tomography (CT) (14). In this study, we selected gallium-68 \(^{68}\text{Ga}\) as the high-energy positron-emitter radioisotope because it is an interesting and common PET radiotracer with a physical half-life of 68 min, a time long enough for imaging acquisition yet short enough for safe radioprotection of both patients and medical staff (15). In addition, generation of clinically used radioactive \(^{68}\text{Ga(III)}\) can be conveniently achieved using homemade facilities for on-demand production via a \(^{68}\text{Ge}/^{68}\text{Ga}\) generator. It should be noted that a chelator is required to enable stable \(^{68}\text{Ga(III)}\) radiolabeling for PET imaging (16). We therefore opted for 1,4,7-triazacyclononane-1,4,7-triacetic acid (NOTA) as the Ga(III) chelator because of its advantages over the commonly used 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid (DOTA). In fact, NOTA chelates Ga(III) with superior thermodynamic stability and kinetic inertness (17) than DOTA, thanks to the perfect match of size, geometry, and denticity between the NOTA macrocycle and the small radionuclide Ga(III). This, in turn, is reflected in favorable enthalpic and entropic contributions to the chelation (18). Also, NOTA is able to complex Ga(III) rapidly and efficiently at room temperature and has high stability in vivo (16, 19). Given the large size of the NOTA macrocycle, to avoid eventual synthetic difficulty (20–22) and instability stemming from possible steric congestion of the dendrimer terminals, we chose to focus on the lowest generation amphiphilic dendrimer 1, which bears four NOTA terminals and one hydrophobic alkyl chain (Fig. 1). This small amphiphilic dendrimer can indeed self-assemble into stable and uniform nanomicelles, which effectively accumulate in tumors via the EPR effect, leading to specific and sensitive imaging of tumors. Most importantly, this dendrimer nanosystem is able to detect, with exceedingly high signal-to-noise ratios, the imaging-refractory low-glucose-uptake tumors that are otherwise difficult to image using the clinical gold reference 2-fluorodeoxyglucose (\([^{18}\text{F}]\text{FDG}\)). This original supramolecular imaging system based on self-assembling amphiphilic dendrimer therefore constitutes a promising nanoplatform for cancer imaging and detection.

The Inset shows the calculated isotopic pattern. (C) Isothermal titration calorimetry (ITC) curve for chelation of \text{Ga}^{3+} with dendrimer 1. The Inset shows measured heat power versus time elapsed during titration.
Results and Discussion

Amphiphilic Dendrimer 1 Bearing NOTA Terminals Is Able to Complex with Ga(III) and Self-Assemble into Small and Uniform Nanomicelles.

The NOTA-bearing dendrimer 1 devised for PET imaging in this work was synthesized starting with the amine-terminated amphiphilic dendrimer, which was conjugated with the reagent NODA-Ga(tBu)₃, followed by subsequent deprotection. The dendrimer 1 was obtained with an excellent overall yield of 83% (Fig. 2A and SI Appendix, Scheme S1B), and its chemical structure was confirmed using ¹H, ¹³C, and 2D NMR and high-resolution mass spectrometry (HRMS), which revealed the characteristic signals corresponding to the chemically conjugated NOTA entities (SI Appendix, Figs. S1 and S2A). The characteristic signals for NOTA moieties in 1 could not be observed when simply mixing the amine-terminating dendrimer with the NOTA reagent in the absence of the coupling agent. This indicates the successful covalent conjugation of the NOTA functionality on the dendrimer terminals. Chelation of the isotope ⁶⁹Ga³⁺ by 1 using ⁶⁹GaCl₃ (Fig. 2A and SI Appendix, Scheme S1B), followed by dialysis to remove free ⁶⁹Ga³⁺, yielded the non-radioactive dendrimer [⁶⁹Ga]Ga-1. HRMS showed the isotopic pattern characteristic of the triply charged species [[⁶⁹Ga]Ga-1]⁺ in addition to the molecular weight peak (Fig. 2B and SI Appendix, Fig. S2B), confirming the successful complexation of four ⁶⁹Ga(III) ions within the dendrimer 1. Since ⁶⁹Ga³⁺ possesses a quadrupolar moment and very low NMR sensitivity (23), well-resolved NMR spectra for [⁶⁹Ga]Ga-1 could not be obtained. We therefore further studied [⁶⁹Ga]Ga-1 using isothermal titration...
Motivated by the favorable self-assembling properties of [68Ga]Ga-1, we prepared the corresponding radioactive dendrimer [68Ga]Ga-1 for PET imaging. Using freshly generated [68Ga]GaCl3, the [68Ga]Ga-1 complex was obtained with a radiochemical purity of 91.9 ± 2.3% soon after synthesis (SI Appendix, Fig. S4A). In addition, radiolabeling was stable up to 2 h after synthesis at room temperature and at 37 °C, both in 0.9% NaCl solution and in human serum (SI Appendix, Fig. S4B). The [68Ga]Ga-1 complex therefore satisfies the two important prerequisites for PET imaging, namely, high radiochemical purity and stability.

We then carried out PET imaging using the self-assembled nanomicelles of [68Ga]Ga-1 to quantify their tumor targeting and uptake in various xenograft mouse models of cancer, including human prostate carcinoma (22Rv1 cell line; Fig. 4A), human glioblastoma (U87 cell line; Fig. 4B), human colorectal adenocarcinoma (HT-29 cell line; Fig. 4C), and human pancreatic adenocarcinoma (SOJ-6 cell line; Fig. 4D). In almost all cases, the observed effective tumor uptake and tumor-to-background ratios with [68Ga]Ga-1 were superior to those obtained with [18F]FDG,
the clinical gold reference for PET imaging in oncology (Fig. 4). $[^{18}F]$FDG PET is based on the high consumption of glucose needed by the fast proliferating and nutrient-greedy cancer cells, and the major drawback of $[^{18}F]$FDG is its physiological accumulation in tissues with high glucose consumption, like myocardium and brain (26), which increases the background signal and has a negative impact on the image quality. It should also be mentioned that certain tumors have low $[^{18}F]$FDG uptake, including tumors derived from human glioblastoma U87 cells and human pancreatic adenocarcinoma SOJ-6 cells. Remarkably, our $[^{68}Ga]$Ga-I nanoparticles had no preferential accumulation in the brain and a low uptake in the heart in all cases. Also, $[^{68}Ga]$Ga-I successfully imaged tumors with both high and low $[^{18}F]$FDG uptake, and the PET signal ratios were up to 14-fold higher with $[^{68}Ga]$Ga-I nanoparticles than with $[^{18}F]$FDG (Fig. 4). Therefore, we reasoned that the difference in $[^{18}F]$FDG and $[^{68}Ga]$Ga-I nanoparticle-based imaging could be ascribed to different tumor uptake mechanisms, with EPR-based tumor accumulation being the most plausible one for the uptake of $[^{68}Ga]$Ga-I.

EPR-Based Tumor Uptake of $[^{68}Ga]$Ga-I for Effective PET Imaging. To investigate the uptake mechanism and obtain evidence for the EPR-based tumor accumulation of $[^{68}Ga]$Ga-I, we carried out a comparative study of PET imaging for tumor detection using the dendrimer nanosystem $[^{68}Ga]$Ga-I and the small molecular complex $[^{68}Ga]$Ga-NOTA (SI Appendix, Scheme S1A) in three pancreatic cancer models, namely, ectopic SOJ-6- and LIPC-xenografted mice (Fig. 5 A and B) and orthotopic SOJ-6-xenografted mice (Fig. 5C). $[^{18}F]$FDG was used as the reference control in all studies. Co-registration with CT enabled precise, anatomical localization of PET signals for further quantification in tumors. The overall excellent tumor-to-background ratios highlighted the high quality of images and tumor targeting obtained with the $[^{68}Ga]$Ga-I nanosystem. Indeed, the tumor uptake of the $[^{68}Ga]$Ga-I nanoparticles was significantly higher than that of the simple $[^{68}Ga]$Ga-NOTA complex and the clinical reference $[^{18}F]$FDG (up to 100-fold increase) not only in the two ectopic pancreatic cancer mouse models (Fig. 5 A and B) but also in the orthotopic pancreatic cancer model (Fig. 5C). Moreover, we observed a significant negative correlation between the tumor uptake of $[^{68}Ga]$Ga-I and tumor blood flow as measured by 3D-Doppler (Fig. 5D). This suggests that $[^{68}Ga]$Ga-I is more likely to accumulate in low-turbulent blood flow tumors, where the EPR effect contribution takes effect (27, 28). These results demonstrated that the significantly enhanced tumor uptake and the resulting superior imaging quality of $[^{68}Ga]$Ga-I indeed stem from the nanoparticle-based EPR effect of the tumor microenvironment, which is distinctly different from the uptake mechanism of $[^{18}F]$FDG. The different uptake mechanisms of $[^{68}Ga]$Ga-I and $[^{18}F]$FDG mean that these two agents can be used in a complementary manner for tumor imaging, with $[^{68}Ga]$Ga-I offering superior imaging, especially for the tumors that are otherwise undetectable using the clinical reference $[^{18}F]$FDG.

Advantageous Pharmacokinetics and Safety Profile of $[^{68}Ga]$Ga-I for PET Imaging. Encouraged by these promising PET imaging results of $[^{68}Ga]$Ga-I, we further studied the pharmacokinetics and biodistribution of $[^{68}Ga]$Ga-I in the orthotopic xenograft mice using μPET dynamic acquisitions (Fig. 6). This allowed us to trace and quantify the distribution of $[^{68}Ga]$Ga-I across body organs from 5 min up to 2 h postinjection. Unlike drug delivery procedures, which require a constant supply of drug to the target tissue, bioimaging demands a rather rapid and intense accumulation of the imaging agent within tumor lesions and a fast clearance of the nonspecific, nonfixed radionuclide. By virtue of its distinct nanostructure, $[^{68}Ga]$Ga-I has a biological elimination half-life of 171 ± 42 min, as obtained from pharmacokinetic analysis of $[^{68}Ga]$Ga-I in blood samples (SI Appendix, Fig. S5). This biological half-life of $[^{68}Ga]$Ga-I is particularly advantageous for PET imaging, as it allows effective image capture shortly after its administration (29, 30). This feature, coupled with the short physical half-life of $[^{68}Ga]$Ga (68 min), allows for both rapid and optimal imaging and fast elimination of radioactivity from the body. Further studies showed that the uptake of $[^{68}Ga]$Ga-I in tumors was steadily increased, while that in the liver was significantly decreased within the 2-h imaging period (Fig. 6). This finding is also in line with the characteristic size and charge features of the $[^{68}Ga]$Ga-I nanoparticles. Indeed, their nanosize allowed them to be readily trapped and enriched in the tumor via the EPR effect, and in the liver through the reticuloendothelial system, whereas their elimination was balanced between the kidneys and the intestines (Fig. 6). Collectively, the combination of high tumor signal stemming from the EPR effect, short biological half-life, and the absence of accumulation in most of the organs except the liver, all contribute to the favorable pharmacokinetic properties of the $[^{68}Ga]$Ga-I nanoparticles for PET imaging of tumors.

It should be mentioned that, during the experimental period, the mice receiving $[^{68}Ga]$Ga-I did not show any abnormal behavior or adverse effects. Healthy mice administered with $[^{68}Ga]$Ga-I showed no cytokine induction, neither blood biochemistry defects nor organ damage, even when the administered dose of $[^{68}Ga]$Ga-I was 10 times higher than the PET imaging dose (SI Appendix, Figs. S6–S8). These results confirm that $[^{68}Ga]$Ga-I is devoid of toxic effects while delivering superior PET imaging quality.
Conclusions

In this work, we have established an effective and excellent self-assembling supramolecular dendrimer nanosystem capable of EPR-based tumor accumulation and PET imaging in various ectopic and orthotopic tumor-xenograft mouse models. Remarkably, the obtained PET images showed significantly higher quality in terms of sensitivity, specificity, and accuracy compared with the clinical reference $[^{18}F]$FDG and the small molecular $[^{68}Ga]$ Ga-NOTA complex. Most importantly, this dendrimer system can detect imaging-refractory low–glucose-uptake tumors that are otherwise undetectable using $[^{18}F]$FDG. In addition, it is endowed with an excellent safety profile and favorable pharmacokinetics for PET imaging, highlighting its potential application for tumor imaging. It is also noteworthy that, until now, there has been no PET nanotracer currently available in oncology, although several have entered in clinical trials (31–33). It will be interesting to compare our dendrimer nanosystem with these reported PET nanotracers to further validate its imaging performance and potential for clinical translation. We will strive in our efforts in this direction.

It is important to note that the results reported in this study provide evidence that self-assembling dendrimer nanosystems hold promise as robust platforms for the delivery of agents in biomedical imaging. These nanosystems can potentially be extended to other imaging modalities such as single-photon emission computed tomography (SPECT) and magnetic resonance imaging (MRI) as well as to combined imaging–therapy applications such as those based on radiotherapy and imaging with the radionuclide $[^{177}Lu]$. The possibility of controlling the chemistry, the size, and the hydrophobicity–hydrophilicity balance of amphiphilic dendrimers (7, 9, 34) provides us with a unique opportunity to fine-tune the self-assembling feature to create functional supramolecular nanosystems for on-demand delivery of different imaging and therapeutic agents for a diverse range of imaging modalities and combined imaging–therapy applications (8, 35, 36). This will offer a particularly interesting perspective on the design and construction of tailor-made self-assembling dendrimer nanosystems for various biomedical applications in general.

Materials and Methods

A full description of the materials and methods is provided in the SI Appendix, including preparation and characterization of 1, $[^{68}Ga]$Ga-1, $[^{68}Ga]$Ga-NOTA, and $[^{68}Ga]$Ga-1, as well as PET imaging of different xenograft mice along with the pharmacokinetics and toxicity evaluation. These include NMR, HRMS, TEM, DLS, CMC, ITC, cell imaging, cell culture, animal xenograft, PET/CT imaging, biodistribution, blood biochemistry, immunotoxicity, and histopathological analysis. Additional figures include synthesis and characterization of 1 and $[^{68}Ga]$Ga-1 (SI Appendix, Figs. 51 and 52 and Scheme 51), nanoparticle stability, radiolabeling purity and stability of $[^{68}Ga]$Ga-1 (SI Appendix, Fig. S5), cytokine induction and serum biochemistry as well as histopathological analysis of main organs (SI Appendix, Figs. S6–S8) of mice treated with 1 and $[^{68}Ga]$Ga-1. All procedures involving animals were performed in accordance with protocols approved by the Institution’s Animal Care and Use Committees at Aix-Marseille University or Peking University.
